Abstract

We model the demand-pressure effect on prices when options cannot be perfectly hedged. The model shows that demand pressure in one option contract increases its price by an amount proportional to the variance of the unhedgeable part of the option. Similarly, the demand pressure increases the price of any other option by an amount proportional to the covariance of their unhedgeable parts. Empirically, we identify aggregate positions of dealers and end users using a unique dataset, and show that demand-pressure effects help explain well-known option-pricing puzzles. First, end users are net long index options, especially out-of-money puts, which helps explain their apparent expensiveness and the smirk. Second, demand patterns help explain the cross section of prices and skews of single-stock options.

∗We are grateful for helpful comments from Apoorva Koticha and especially from Steve Figlewski, as well as from seminar participants at New York University and University of Pennsylvania

1 Introduction

“Skew is heavily influenced by supply and demand factors”
— Gray, director of global equity derivatives, Dresdner Kleinwort Benson

“The number of players in the skew market is limited. ... there’s a huge imbalance between what clients want and what professionals can provide.”
— Belhadj-Soulami, head of equity derivatives trading for Europe, Paribas

“To blithely attribute divergences between objective and risk-neutral probability measures to the free ‘risk premium’ parameters within an affine model is to abdicate one’s responsibilities as a financial economist. ... a renewed focus on the explicit financial intermediation of the underlying risks by option market makers is needed.”

We take on this challenge by providing a model of option intermediation, and by showing empirically using a unique dataset that demand pressure can help explain the main option-pricing puzzles.

The starting point of our analysis is that options are traded because they are useful and, therefore, options cannot be redundant for all investors (Hakansson (1979)). We denote the agents who have a fundamental need for option exposure as “end users.”

Intermediaries such as market makers and proprietary traders provide liquidity to end users by taking the other side of the end-user net demand. If intermediaries can hedge perfectly — as in a Black-Scholes-Merton economy — then option prices are determined by no-arbitrage and demand pressure has no effect. In reality, however, even intermediaries cannot hedge options perfectly because of rebalancing over discrete time intervals, stochastic volatility, and transaction costs (Figlewski (1989)).

To capture this effect, we consider a model of competitive risk-averse dealers who trade at discrete times. The dealers trade many option contracts on the same underlying such that certain risks net out, while others do not. Further, dealers can hedge derivative positions by trading the underlying security. We consider a general class of distributions for the underlying, which can accommodate stochastic volatility and jumps. Dealers trade with end users. The model is agnostic about the end users’ reasons for trade.

We compute equilibrium prices as functions of demand pressure, that is, the prices that make dealers optimally choose to supply the options that the end users demand. We show explicitly how demand pressure enters into the pricing kernel. Intuitively, a positive demand pressure in an option increases the pricing kernel in the states of nature in which an optimally hedged position has a positive payoff. This pricing-kernel

\[^{1}\text{Also, traders have capital constraints as emphasized, e.g., by Shleifer and Vishny (1997).}\]
effect increases the price of the option, which entices the dealers to sell it. Specifically, a marginal change in demand pressure in an option contract increases its price by an amount proportional to the variance of the unhedgeable part of the option, where the variance is computed under a certain probability measure. Similarly, the demand pressure increases the price of any other option by an amount proportional to the covariance of their unhedgeable parts. Hence, while demand pressure in a particular option raises its price, it also raises the price of other options with the same underlying, especially similar contracts.

Empirically, we use a unique dataset to identify aggregate daily positions of dealers and end users. In particular, we define dealers as marketmakers and proprietary traders and end users as customers of brokers. We find that end users have a net long position in S&P500 index options with the largest net position in out-of-money puts. Hence, since options are in zero net supply, dealers are short index options. While it is conventional wisdom among option traders that Wall Street is short index volatility, this paper is the first to demonstrate this fact using data on option holdings. This can help explain the puzzle that index options appear to be expensive, and that low-moneyness options seem to be especially expensive (Longstaff (1995), Bates (2000), Coval and Shumway (2001), Amin, Coval, and Seyhun (2003), Bondarenko (2003)). In the time series, demand for index options is related to their expensiveness, measured for instance by the difference between their implied volatility and recent historical volatility. Further, the steepness of the smirk, measured by the difference between the implied volatility of low-moneyness options and at-the-money options, is positively related to the skew of option demand, measured by the demand of low-moneyness options minus the demand of high-moneyness options.

Jackwerth (2000) finds that a representative investor’s option-implied utility function is inconsistent with standard assumptions in economic theory. Since options are in zero net supply, a representative investor holds no options. We reconcile this finding for dealers who have significantly short index options positions. Intuitively, an investor will short index options, but only a finite number of options. Hence, while a standard-utility investor may not be marginal on options given a zero position, he is marginal given a certain negative position. We do not address why end users buy these options; their motives could be related to portfolio insurance and agency problems (e.g. between investors and fund managers) that are not well captured by standard utility theory.

Another option-pricing puzzle is that index option prices are so different from the prices of single-stock options despite the fact that the distributions of the underlying appear relatively similar (e.g. Bollen and Whaley (2004)). In particular, single-stock options appear cheaper and their smile is flatter. Consistently, we find that the demand pattern for single-stock options is very different from that of index options. For

\footnote{See also Driessen and Maenhout (2003).}
instance, end users are net short single stock options — not long as with index options.

Demand patterns further help explain the cross-sectional pricing of single-stock options. Indeed, stocks with high (negative) demand for options, aggregated across contracts, tend to have relatively expensive (cheap) options. Further, stocks in which the option demand is skewed towards low-moneyness options tend to have a larger difference between the implied volatility of low-moneyness options and at-the-money options.

The paper is related to several strands of literature. First, the literature on option pricing in the context of trading frictions and incomplete markets derives bounds on option pricing. Arbitrage bounds are trivial with any transactions costs; for instance, the price of a call option can be as high as the price of the underlying stock (Soner, Shreve, and Cvitanic (1995)). Cochrane and Saa-Requejo (2000) and Bernardo and Ledoit (2000) derive tighter option-pricing bounds by restricting the Sharpe ratio or gain/loss ratio to be below an arbitrary level, and Constantinides and Perrakis (2002) derive bounds using stochastic dominance for small option positions. Rather than deriving bounds, we compute explicit prices based on the demand pressure by end users. We further complement this literature by taking portfolio considerations into account, that is, the effect of demand in one options on the price of other options.

Second, the literature on utility-based option pricing (“indifference pricing”) derives the option price that would make an agent (e.g. the representative agent) indifferent between buying the option or not. See Rubinstein (1976), Brennan (1979), Stapleton and Subrahmanyam (1984), Hugonnier, Kramkov, and Schachermayer (2004) and references therein. While this literature computes the price of the first “marginal” option demanded, we show how option prices change when demand is non-trivial.

Third, our results are important for the literature on behavioral option pricing. Stein (1989) and Poteshman (2001) provide evidence that option investors misproject changes in the instantaneous volatility of underlying assets by examining the price changes of shorter and longer maturity options. Our paper shows how the cognitive biases of option end users can translate (via their option demands) into option mispricing even if market makers are not subject to any behavioral biases. By contrast, under standard models like Black-Scholes-Merton, market makers who can hedge their positions perfectly will correct the mistakes of other option market participants before they effect option prices. As a result, this paper provides a foundation for the application of behavioral finance to the option market.

Fourth, since our model is general and can in principle be applied to any market, our work is related to the broader literature on demand pressure effects. Consistent with our model’s predictions, Wurgler and Zhuravskaya (2002) find that stocks that are hard to hedge experience larger price jumps when included into the S&P 500 index. Greenwood (2005) considers a major redefinition of the Nikkei 225 index in Japan and finds that stocks that are not affected by demand shocks, but correlated with securities facing demand shocks, experience price changes. Similarly in the fixed income market,

The most closely related paper is Bollen and Whaley (2004) which demonstrates that changes in implied volatility are correlated with signed option volume. These empirical results set the stage for our analysis by showing that changes in option demand lead to changes in option prices while leaving open the question of whether the level of option demand impacts the overall level (i.e., expensiveness) of option prices or the overall shape of implied volatility curves. We complement Bollen and Whaley (2004) by providing a theoretical model and by investigating empirically the relationship between the level of end user demand for options and the level and overall shape of implied volatility curves. In particular, we document that end users tend to have a net long SPX option position and a short equity option position, thus helping to explain the relative expensiveness of index options. We also show that there is a strong downward skew in the net demand of index but not equity options which helps to explain the difference in the shapes of their overall implied volatility curves.

The rest of the paper is organized as follows. Section 2 describes the model, and Section 3 derives its pricing implications. Section 4 explains our data and provides descriptive statistics on demand patterns for options. Section 5 provides our empirical analysis of the effect of demand pressure on option prices, while Section 6 concludes. The appendix contains proofs.

2 A Model of Demand Pressure

We consider a discrete-time infinite-horizon economy. There exists a risk-free asset paying interest at the rate of $r - 1$ per period, and a risky security that we refer to as the “underlying” security. At time $t$, the underlying has an exogenous price of $S_t$, dividend $D_t$, and an excess return of $R^e_t = (S_t + D_t)/S_{t-1} - r$ and the distribution of future prices and returns is characterized by a stationary Markov state variable $X_t \in X \subset \mathbb{R}^n$, with $X$ compact. (The state variable could include the current level of volatility, the current jump intensity, etc.) The only condition we impose on the transition function $\pi : X \times X \to \mathbb{R}_+$ of $X$ is that it have the Feller property.

---

3Indeed, Bollen and Whaley (2004) find that a nontrivial part of the option price impact from day $t$ signed option volume dissipates by day $t + 1$.

4All random variables are defined on a probability space $(\Omega, \mathcal{F}, P_r)$ with an associated filtration $\{\mathcal{F}_t : t \geq 0\}$ of sub-$\sigma$-algebras representing the resolution over time of information commonly available to agents.

5This condition can be relaxed at the expense of further technical complexity.
The economy further has a number of “derivative” securities, whose prices are to be determined endogenously. A derivative security is characterized by its index \( i \in I \), where \( i \) collects the information that identifies the derivative and its payoffs. For a European option, for instance, the strike price, maturity date, and whether the option is a “call” or “put” suffice. The set of derivatives traded at time \( t \) is denoted by \( I_t \), and the vector of prices of traded securities is \( p_t = (p^i_t)_{i \in I_t} \).

We assume that the payoffs of the derivatives depend on \( S_t \) and \( X_t \). We note that the theory is completely general and does not require that the “derivatives” have payoffs that depend on the underlying. In principle, the derivatives could be any securities whose prices are affected by demand pressure.

The economy is populated by two kinds of agents: “dealers” and “end users.” Dealers are competitive and there exists a representative dealer who has constant absolute risk aversion, that is, his utility for remaining lifetime consumption is:

\[
U(C_t, C_{t+1}, \ldots) = E_t \left[ \sum_{v=t}^{\infty} \rho^{v-t} u(C_v) \right],
\]

where \( u(c) = -\frac{1}{2} e^{-\gamma c} \) and \( \rho \in \mathbb{R} \) is a discount factor. At any time \( t \), the dealer must choose the consumption \( C_t \), the dollar investment in the underlying \( \theta_t \), and the number of derivatives held \( q_t = (q^i_t)_{i \in I_t} \), while satisfying the transversality condition \( \lim_{t \to \infty} E \left[ \rho^{-t} e^{-kW_t} \right] = 0 \), where the dealer’s wealth evolves as

\[
W_{t+1} = y_{t+1} + (W_t - C_t)r + q_t(p_{t+1} - rp_{t}) + \theta_t R^c_{t+1},
\]

\( k = \gamma(r - 1)/r \), and \( y_t \) is the dealer’s time-\( t \) endowment. We assume that the distribution of future endowments is characterized by \( X_t \).

In the real world, end users trade options for a variety of reasons such as portfolio insurance, agency reasons, behavioral reasons, institutional reasons etc. Rather than trying to capture these various trading motives endogenously, we assume that end users have an exogenous aggregate demand for derivatives of \( d_t = (d^i_t)_{i \in I_t} \) at time \( t \). We assume that \( R^c_t, D_t/S_t, y_t, \) and \( d_t \) are continuous functions of \( X_t \). Furthermore, for technical reasons, we assume that, after some time \( T \), demand pressure is zero, that is, \( d_t = 0 \) for \( t > T \).

Derivative prices are set through the interaction between dealers and end users in a competitive equilibrium.

**Definition 1** A price process \( p_t = p_t(d_t, X_t) \) is a (competitive Markov) equilibrium if, given \( p \), the representative dealer optimally chooses a derivative holding of \( q \) such that derivative markets clear \( q + d = 0 \).

Our asset pricing approach relies on the insight that, by observing the aggregate quantities held by dealers, we can determine the derivative prices consistent with the
dealers’ utility maximization. Our goal is to determine how derivative prices depend on 
the demand pressure \( d \) coming from end users. We note that it is not crucial that end 
users have inelastic demand. All that matters is that end users have demand curves 
that result in dealers holding a position of \( q = -d \).

To determine the representative dealer’s optimal behavior, we consider his value 
function \( J(W; X, t) \), which depends on his wealth \( W \), the state of nature \( X \), and time 
\( t \). Then, the dealer solves the following maximization problem:

\[
\max_{C_t, q_t, \theta_t} -\frac{1}{\gamma} e^{-\gamma C_t} + \rho E_t[J(W_{t+1}; t+1, X_{t+1})] \\
\text{s.t. } W_{t+1} = y_{t+1} + (W_t - C_t) r + q_t (p_{t+1} - r p_t) + \theta_t R^e_{t+1}.
\]

(1)

(2)

The value function is characterized in the following proposition.

**Lemma 1** If \( p_t = p_t(d_t, X_t) \) is the equilibrium price process and \( k = \frac{2(r+1)}{r} \), then the 
dealer’s value function and optimal consumption are given by

\[
J(W_t; t, X_t) = -\frac{1}{k} e^{-k(W_t + f_t(d_t, X_t))}
\]

(3)

\[
C_t = \frac{k}{\gamma} (W_t + f_t(d_t, X_t))
\]

(4)

and the stock and derivative holdings are characterized by the first-order conditions

\[
0 = E_t \left[ e^{-k(y_{t+1} + \theta_t R^e_{t+1} + q_t (p_{t+1} - r p_t) + f_{t+1}(d_{t+1}, X_{t+1}))} R^e_{t+1} \right]
\]

(5)

\[
0 = E_t \left[ e^{-k(y_{t+1} + \theta_t R^e_{t+1} + q_t (p_{t+1} - r p_t) + f_{t+1}(d_{t+1}, X_{t+1}))} (p_{t+1} - r p_t) \right],
\]

(6)

where, for \( t \leq T \), the function \( f_t(d_t, X_t) \) is derived recursively using (5), (6), and

\[
e^{-kr f_t(d_t, X_t)} = r \rho E_t \left[ e^{-k(y_{t+1} + q_t (p_{t+1} - r p_t) + \theta_t R^e_{t+1} + f_{t+1}(d_{t+1}, X_{t+1}))} \right]
\]

(7)

and for \( t > T \), the function \( f_t(d_t, X_t) = \bar{f}(X_t) \) where \( (\bar{f}(X_t), \bar{\theta}(X_t)) \) solves

\[
e^{-kr \bar{f}(X_t)} = r \rho E_t \left[ e^{-k(y_{t+1} + \bar{\theta}_t R^e_{t+1} + \bar{f}(X_{t+1}))} \right]
\]

(8)

\[
0 = E_t \left[ e^{-k(y_{t+1} + \bar{\theta}_t R^e_{t+1} + \bar{f}(X_{t+1}))} R^e_{t+1} \right].
\]

(9)

The optimal consumption is unique and the optimal security holdings are unique pro-
vided their payoffs are linearly independent.

While dealers compute optimal positions given prices, we are interested in inverting 
this mapping and compute the prices that make a given position optimal. The following 
proposition ensures that this inversion is possible.
Proposition 1 Given any demand pressure process \( d \) for end users, there exists a unique equilibrium \( p \).

Before considering explicitly the effect of demand pressure, we make a couple of simple “parity” observations that show how to treat derivatives that are linearly dependent such as puts and calls with the same strike and maturity. For simplicity, we do this only in the case of a non-dividend paying underlying, but the results can easily be extended. We consider two derivatives, \( i \) and \( j \) such that a non-trivial linear combination of their payoffs lies in the span of exogenously-priced securities, i.e., the underlying and the bond. In other words, suppose that at the common maturity date \( T \),

\[
p^i_T = \lambda p^j_T + \alpha + \beta S_T
\]

for some constants \( \alpha, \beta, \) and \( \lambda \). Then it is easily seen that, if positions \((q^i_t, q^j_t, b_t, \theta_t)\) in the two derivatives, the bond, and the underlying, respectively, are optimal given the prices, then so are positions \((q^i_t + a, q^j_t - \lambda a, b_t - a\alpha r^{-(T-t)}, \theta_t - a\beta S^{-1}_t)\). This has the following implications for equilibrium prices:

Proposition 2 Suppose that \( \text{DF}_t = 0 \) and \( p^i_T = \lambda p^j_T + \alpha + \beta S_T \). Then:

(i) For any demand pressure, \( d \), the equilibrium prices of the two derivatives are related by

\[
p^i_t = \lambda p^j_t + \alpha r^{-(T-t)} + \beta S_t.
\]

(ii) Changing the end user demand from \((d^i_t, d^j_t)\) to \((d^i_t + a, d^j_t - \lambda a)\), for any \( a \in \mathbb{R} \), has no effect on equilibrium prices.

The first part of the proposition is general version of the well-known put-call parity. It shows that if payoffs are linearly dependent then so are prices.

The second part of the proposition shows that linearly dependent derivatives have the same demand-pressure effects on prices. Hence, in our empirical exercise, we can aggregate the demand of calls and puts with the same strike and maturity. That is, a demand pressure of \( d^i \) calls and \( d^j \) puts is the same as a demand pressure of \( d^i + d^j \) calls and 0 puts (or vice versa).

3 Price Effects of Demand Pressure

We now consider the main implication of the theory, namely how demand pressure affects prices. Our goal is to compute security prices \( p^i_t \) as functions of the current demand pressure \( d^i_t \) and the state variable \( X_t \) (which incorporates beliefs about future demand pressure).

\(^6\)This is a dollar amount; equivalently, we may assume that the price of the bond is always 1.
We think of the price $p$, the hedge position $\theta_t$ in the underlying and the consumption function $f$ as functions of $d_t^i$ and $X_t$. Alternatively, we can think of the dependent variables as function of the dealer holding $q_t^i$ and $X_t$, keeping in mind the equilibrium relation that $q = -d$. For now we use this latter notation.

At maturity date $T$, an option has a known price $p_T$. At any prior date $t$, the price $p_t$ can be found recursively by “inverting” (6) to get

$$p_t = \frac{E_t \left[ e^{-k(y_t+\theta_t R_{t+1}^e+q_t p_{t+1}+f_t+1)} p_{t+1} \right]}{r E_t \left[ e^{-k(y_t+\theta_t R_{t+1}^e+q_t p_{t+1}+f_t+1)} \right]} \tag{10}$$

where the hedge position in the underlying, $\theta_t$, solves

$$0 = E_t \left[ e^{-k(y_t+\theta_t R_{t+1}^e+q_t p_{t+1}+f_t+1)} R_{t+1}^e \right] \tag{11}$$

and where $f$ is computed recursively as described in Lemma 1. Equations (10) and (11) can be written in terms of a demand-based pricing kernel:

**Theorem 1** Prices $p$ and the hedge position $\theta$ satisfy

$$p_t = E_t (m_{t+1}^d p_{t+1}) = \frac{1}{r} E_t^d(p_{t+1}) \tag{12}$$

$$0 = E_t (m_{t+1}^d R_{t+1}^e) = \frac{1}{r} E_t^d(R_{t+1}^e) \tag{13}$$

where the pricing kernel $m^d$ is a function of demand pressure $d$:

$$m_{t+1}^d = \frac{e^{-k(y_t+\theta_t R_{t+1}^e+q_t p_{t+1}+f_t+1)}}{r E_t \left[ e^{-k(y_t+\theta_t R_{t+1}^e+q_t p_{t+1}+f_t+1)} \right]} \tag{14}$$

$$= \frac{e^{-k(y_t+\theta_t R_{t+1}^e-d_t p_{t+1}+f_t+1)}}{r E_t \left[ e^{-k(y_t+\theta_t R_{t+1}^e-d_t p_{t+1}+f_t+1)} \right]} \tag{15}$$

and $E_t^d$ is expected value with respect to the corresponding risk-neutral measure, i.e. the measure with a Radon-Nykodim derivative of $r m_{t+1}^d$.

To understand this pricing kernel, suppose for instance that end users want to sell derivative $i$ such that $d_t^i < 0$, and that this is the only demand pressure. In equilibrium, dealers take the other side of the trade, buying $q_t^i = -d_t^i > 0$ shares of this derivative, while hedging their position using a position of $\theta_t$ in the underlying. The pricing kernel is small whenever the “unhedgeable” part $q_t p_{t+1} + \theta_t R_{t+1}^e$ is large. Hence, the pricing kernel assigns a low value to states of nature in which a hedged position in the derivative pays off profitably, and it assigns a high value to states in which a hedged
position in the derivative has a negative payoff. This pricing kernel-effect decreases the price of this derivative, which is what entices the dealers to buy it.

It is interesting to consider the first-order effect of demand pressure on prices. Hence, we calculate explicitly the sensitivity of the prices of a derivative $p_t^i$ with respect to the demand pressure of another derivative $d_t^j$. We can initially differentiate with respect to $q$ rather than $d$ since $q^i = -d_t^j$.

For this, we first differentiate the pricing kernel\(^7\)

$$\frac{\partial m_{t+1}^d}{\partial q_t^j} = -km_{t+1}^d \left( p_t^j - np_t^j + \frac{\partial \theta_t}{\partial q_t^j} R_{t+1}^c \right)$$

(16)

using that $\frac{\partial f(t+1, X_{t+1}, y_t)}{\partial q_t^j} = 0$ and $\frac{\partial r_{t+1}}{\partial q_t^j} = 0$. With this result, it is straightforward to differentiate (13) to get

$$0 = E_t \left( m_{t+1}^d \left( p_t^j - np_t^j + \frac{\partial \theta_t}{\partial q_t^j} R_{t+1}^c \right) R_{t+1}^c \right)$$

(17)

which implies that the marginal hedge position is

$$\frac{\partial \theta_t}{\partial q_t^j} = -\frac{E_t \left( m_{t+1}^d \left( p_t^j - np_t^j + \frac{\partial \theta_t}{\partial q_t^j} R_{t+1}^c \right) R_{t+1}^c \right)}{E_t \left( m_{t+1}^d (R_{t+1}^c)^2 \right)} = -\frac{\text{Cov}_t^d(p_{t+1}^j, R_{t+1}^c)}{\text{Var}_t^d(R_{t+1}^c)}$$

(18)

Similarly, we derive the price sensitivity by differentiating (12)

$$\frac{\partial p_t^j}{\partial q_t^j} = -kE_t \left[ m_{t+1}^d \left( p_t^j - np_t^j + \frac{\partial \theta_t}{\partial q_t^j} R_{t+1}^c \right) \right]$$

(19)

$$= -kE_t \left[ \left( p_t^j - np_t^j - \frac{\text{Cov}_t^d(p_{t+1}^j, R_{t+1}^c)}{\text{Var}_t^d(R_{t+1}^c)} R_{t+1}^c \right) \right]$$

(20)

$$= -\gamma(r-1)E_t \left[ \text{Cov}_t^d \left( \tilde{p}_{t+1}^j, \tilde{p}_{t+1}^j \right) \right]$$

(21)

$$= -\gamma(r-1)\text{Cov}_t^d \left[ \tilde{p}_{t+1}^j, \tilde{p}_{t+1}^j \right]$$

(22)

where $\tilde{p}_{t+1}^j$ and $\tilde{p}_{t+1}^j$ are the unhedgeable parts of the price changes as defined in:

**Definition 2** The unhedgeable price change of any security $k$ is

$$\tilde{p}_{t+1}^k = r^{-1} \left( p_{t+1}^k - r p_t^k - \frac{\text{Cov}_t^d(p_{t+1}^k, R_{t+1}^c)}{\text{Var}_t^d(R_{t+1}^c)} R_{t+1}^c \right).$$

(23)

Equation (22) can also be written in terms of the demand pressure, $d$, by using the equilibrium relation $d = -q$.
Theorem 2 The price sensitivity to demand pressure is

$$\frac{\partial p_i}{\partial d_j} = \gamma(r - 1)E_t(d) (\bar{p}_{t+1} \bar{p}_{t+1}') = \gamma(r - 1)Cov_t(d) (\bar{p}_{t+1} \bar{p}_{t+1}')$$

This result is intuitive: it says that the demand pressure in an option \( j \) increases the option’s own price by an amount proportional to the variance of the unhedgeable part of the option and the aggregate risk aversion of dealers. We note that since a variance is always positive, the demand-pressure effect on the security itself is naturally always positive. Further, this demand pressure affects another option \( i \) by an amount proportional to the covariation of their unhedgeable parts. For European options, we can show, under the condition stated below, that a demand pressure in one option also increases the price of other options on the same underlying:

Proposition 3 Demand pressure in any security \( j \):
(i) increases its own price, that is, \( \frac{\partial p_j}{\partial d_j} \geq 0 \).
(ii) increases the price of another security \( i \), that is, \( \frac{\partial p_i}{\partial d_j} \geq 0 \), provided that \( E_t[d|p_{t+1}|S_{t+1}] \) and \( Cov_t(d|p_{t+1}|S_{t+1}) \) are convex functions of \( S_{t+1} \) and \( Cov_t(d|p_{t+1}, p_{t+1}'|S_{t+1}) \geq 0 \).

The conditions imposed in part (ii) are natural. First, we require that prices inherit the convexity property of the option payoffs in the underlying price. Second, we require that \( Cov_t(d|p_{t+1}, p_{t+1}'|S_{t+1}) \geq 0 \), that is, changes in the other variables have a similar impact on both option prices — for instance, both prices are increasing in the volatility or demand level. Note that both conditions hold if both options mature after one period. The second condition also holds if option prices are homogenous (of degree 1) in \((S, K)\), where \( K \) is the strike, and \( S_t \) is independent of \( X_t \).

It is interesting to consider the total price that end users pay for their demand \( d_t \) at time \( t \). Vectorizing the derivatives from Theorem 2, we can first order approximate the price around a zero demand as follows

$$p_t \approx p_t(d_t = 0) + \gamma(r - 1)E_t(d) (\bar{p}_{t+1} \bar{p}_{t+1}') d_t \quad (24)$$

$$d'_t p_t = d'_tp_t(0) + \gamma(r - 1)Var_t(d) (\bar{p}_{t+1} \bar{p}_{t+1}) \quad (25)$$

Hence, the total price paid for the \( d_t \) derivatives is

$$d'_t p_t = d'_t p_t(0) + \gamma(r - 1)Var_t(d) (\bar{p}_{t+1} \bar{p}_{t+1}) \quad (26)$$

The first term \( d'_t p_t(d_t = 0) \) is the price that end users would pay if their demand pressure did not affect prices. The second term is total variance of the unhedgeable part of all of the end users’ positions.
While Proposition 3 shows that demand for an option increases the prices of all options, the size of the price effect is of course not the same for all options. Under certain conditions, demand pressure in low-strike options has a larger impact on the implied volatility of low-strike options, and conversely for high strike options. The following proposition makes this intuitively appealing result precise. For simplicity, the proposition relies on unnecessarily restrictive assumptions. We let \( p(p, K, d) \), respectively \( p(c, K, d) \), denote the price of a put, respectively a call, with strike price \( K \) and 1 period to maturity, where \( d \) is the demand pressure. It is natural to compare low-strike and high-strike options that are “equally far out of the money.” We do this be considering an out-of-the-money put with the same price as an out-of-the-money call.

**Proposition 4** Assume that the one-period risk-neutral distribution of the underlying return is symmetric and consider demand pressure \( d > 0 \) in an option with strike \( K < rS_t \) that matures after one trading period. Then there exists a value \( \bar{K} \) such that, for all \( K' \leq \bar{K} \) and \( K'' \) such that \( p(p, K', 0) = p(c, K'', 0) \), it holds that \( p(p, K', d) > p(c, K'', d) \). That is, the price of the out-of-the-money put \( p(p, K', \cdot) \) is more affected by the demand pressure than the price of out-of-the-money call \( p(c, K'', \cdot) \). The reverse conclusion applies if there is demand for the a high-strike option.

Future demand pressure in a derivative \( j \) also affects the current price of \( i \). As above, we consider the first-order price effect. This is slightly more complicated, however, since we cannot differentiate with respect to the unknown future demand pressure. Instead, we “scale down” the future demand pressure, that is, we consider a future demand pressures of \( \tilde{d}_s^j = \epsilon d_s^j \) (equivalently, \( \tilde{q}_s^j = \epsilon q_s^j \)) for some \( \epsilon \in \mathbb{R}, s > t, \) and \( j \).

**Theorem 3** Let \( p_t(0) \) denote the equilibrium derivative prices with 0 demand pressure. Fixing a process \( d \) with \( d_t = 0 \) for all \( t > T \) and a given \( T \), the equilibrium prices \( p \) with a demand pressure of \( \epsilon d \) is

\[
p_t = p_t(0) + \gamma (r - 1) \left[ E_t^0 \left( \tilde{p}_{t+1}^j \tilde{p}_{t+1}^i \right) dt + \sum_{s > t} r^{-(s-t)} E_t^0 \left( \tilde{p}_{s+1}^j \tilde{p}_{s+1}^i d_s \right) \right] \epsilon + O(\epsilon^2)
\]

This theorem shows that the impact of current demand pressure \( d_t \) on the price of a derivative \( i \) is given by the amount of hedging risk that a marginal position in security \( i \) would add to the dealer’s portfolio, that is, it is the sum of the covariances of its unhedgeable part with the unhedgeable part of all the other securities, multiplied by their respective demand pressures. Further, the impact of future demand pressures \( d_s \) is given by the expected future hedging risks. Of course, the impact increases with the dealers’ risk aversion.
4 Data

The main focus of this paper is the impact of net end-user option demand on option prices. We explore this impact both for S&P 500 index options and also for equity (i.e., individual stock) options. Consequently, the main data that we employ is that on SPX and equity option demand and prices. Our data period extends from the beginning of 1996 through the end of 2001.\footnote{Options on the S&P 500 index have many different option symbols. In this paper, \textit{SPX options} always refers to all options that have SPX as their underlying asset, not only to those with option symbol SPX.} For the equity options, we limit the underlying stocks to those with strictly positive option volume on at least 80\% of the trade days over the 1996 to 2001 period. This restriction yields 303 underlying stocks.

We acquire the data from two different sources. Data for computing net option demand were obtained directly from the Chicago Board Options Exchange (CBOE). These data consist of a daily record of closing short and long open interest on all SPX and equity options for public customers and firm proprietary traders.\footnote{The total long open interest for any option always equals the total short open interest. For a given investor type (e.g., public customers), however, the long open interest is not equal to the short open interest in general.} The SPX options trade only at the CBOE while the equity options sometimes are cross-listed at other option markets. Our open interest data, however, include activity from all markets at which CBOE listed options trade. The entire option market is comprised of public customers, firm proprietary traders, and market makers. Hence, our data cover all non-market maker option open interest.

Firm proprietary traders sometimes are end-users of options and sometimes are liquidity suppliers. Consequently, we compute net end-user demands for an option in two different ways. First, we assume that firm proprietary traders are end-users and compute the net demand for an option as the sum of the public customer and firm proprietary trader long open interest minus the sum of the public customer and firm proprietary trader short open interest. We refer to net demand computed in this way as \textit{non-market maker net demand}. Second, we assume that the firm proprietary traders are liquidity suppliers and compute the net demand for an option as the public customer long open interest minus the public customer short open interest. We refer to net demand computed in this second way as \textit{public customer net demand}.

Even though the SPX and individual equity option market have been the subject of extensive empirical research, there is not much information on end-user demand in these markets. Consequently, we provide a somewhat detailed description of net demand for SPX and equity options. Over the 1996-2001 period the average daily non-market maker net demand for SPX options is 105,890 contracts, and the average daily public customer net demand is 138,602 contracts. In other words, the typical end-user demand for SPX options during our data period is on the order of 125,000 SPX option contracts.
contracts. For puts (calls), the average daily net demand from non-market makers is 126,514 (−20,624) contracts, while from public customers it is 184,429 (−45,833) contracts. These numbers indicate that most net option demand comes from puts. Indeed, end-users tend to be net suppliers of on the order of 30,000 call contracts.

For the equity options, the average daily non-market maker net demand per underlying stock is −2717 contracts, and the average daily public customer net demand is −4873 contracts. Hence, in the equity option market, unlike the index option market, end users are net suppliers of options. This fact suggests that if demand for options has a first order impact on option prices, index options should on average be more expensive than individual equity options. Another interesting contrast with the index option market is that in the equity option market the net end-user demand for puts and calls is similar. For puts (calls), the average daily non-market maker net demand is −1103 (−1614) contracts, while from public customers it is −2331 (−2543) contracts.

Panel A of Table 1 reports the average daily public customer net demand for SPX options broken down by option maturity and moneyness (defined as the strike price divided by the underlying index level.) Panel A indicates that 28 percent of the non-market maker net demand comes from contracts with fewer than 30 calendar days to expiration. Consistent with conventional wisdom, the good majority of this net demand is concentrated at moneyness where puts are out-of-the-money (OTM) (i.e., moneyness < 1.) It is interesting that more than 37 percent of the net demand in the options with fewer than 30 calendar days to expiration comes from those which are far OTM with moneyness < 0.85. Panel B of Table 1 reports the average option net demand per underlying stock for individual equity options from public customers. With the exception of the very long maturity options (i.e, those with more than one year to expiration) the public customer net demand for all of the moneyness/maturity categories is negative. That is, public customers are net suppliers of options in all of these categories. This stands in stark contrast to the index option market in Panel A where public customers are net demanders of options in almost every moneyness/maturity category.

The other main source of data for this paper is the Ivy DB data set from OptionMetrics LLC. The OptionMetrics data include end-of-day volatilities implied from option prices, and we use the volatilities implied from SPX and CBOE listed equity options from the beginning of 1996 through the end of 2001. SPX options have European style exercise, and OptionMetrics computes implied volatilities by inverting the Black-Scholes formula. When performing this inversion, the option price is set to the midpoint of the best closing bid and offer prices, the interest rate is interpolated from available LIBOR rates so that its maturity is equal to the expiration of the option, and the index’s dividend yield is determined from put-call parity. The equity options have American style exercise, and OptionMetrics computes their implied volatilities using binomial trees which account for the early exercise feature and which assume that investors have perfect foresight of the timing and amount of the dividends paid
by the underlying stock over the life of the options.

One of the central questions we are investigating is whether net demand pressure pushes option implied volatilities away from the volatilities that are expected to be realized over the remainder of the options’ lives. We refer to the difference between implied and expected volatility as *excess implied volatility*. We use three different measures of the expected volatility and get similar results. We use the historical volatility for 60 trade days leading up to the observation of an option price as an ex-ante proxy for this expectation, a GARCH(1,1) estimate as an alternative proxy, and the volatility realized over the life of an option as an ex-post proxy for the expectation.

To compute these volatility estimates directly from the daily returns on the underlying index or stock, we use daily SPX and stock returns from the Center for Research in Security Prices (CRSP). In particular, if we have $N$ consecutive daily returns, we compute the annualized volatility of the SPX index or underlying stock over the $N$ trade days as

$$
\sigma = \sqrt{\frac{252}{N} \sum_{i=1}^{N} R_i^2}
$$

(28)

Note that this method assumes that there are 252 trade days in a year and constrains the mean daily return to be zero as suggested by Figlewski (1997). The GARCH(1,1)

Table 1: Average daily public customer net demand for put and call option contracts for SPX and individual equity options by moneyness and maturity, 1996-2001. Equity option demand is per underlying stock.
estimates are computed in a standard way.

The daily average excess implied volatility for SPX options is 6.6%/6.5%/7.1% when historical/realized/GARCH(1,1) volatility is used as the proxy for the expected volatility. To compute these numbers, on each trade day we average the implied volatilities on all SPX options which have at least 25 contracts of trading volume and then subtract the proxy for expected volatility. Consistent with previous research, on average the SPX options in our sample are expensive. For the equity options, the daily average excess implied volatility per underlying stock is -0.5%/-0.4%/-0.3% when historical/realized/GARCH(1,1) volatility is used as the proxy for the expected volatility over the life of the option. These numbers suggest that on average individual equity options are just slightly inexpensive. Here we required that an option trade at least
contracts and have a closing bid price of at least 12.5 cents in order to include its implied volatility in the calculation.

Figure 1 compares SPX option expensiveness to net demands across moneyness categories. The line in the figure plots the average SPX excess implied volatility (with respect to historical volatility) for eight moneyness intervals over the 1996-2001 period.¹⁰ In particular, on each trade date the average excess implied volatility is computed for all puts and calls in a moneyness interval. The line depicts the means of these daily averages. The excess implied volatility inherits the familiar downward sloping smirk in SPX option implied volatilities.

The bars in Figure 1 present the average daily net demand from public customers for SPX options in the moneyness categories.¹¹ It is clear from the figure that there is a positive relationship between the net demand and the excess implied volatilities which suggests that net demand may cause excess implied volatility. At the same time, the relationship seems to be imperfect. For example, the second highest bar is the one for moneyness between 0.95 and 1.00 while the excess implied volatility for this moneyness category is not especially high. We note, however, that our theory implies that demand pressure in one moneyness category impacts the implied volatility of options in other categories, thus smoothing the implied volatility curve.¹²

We also constructed a figure like Figure 1 except that both the excess implied volatilities and the net demands were computed only from put data. Unsurprisingly, the plot looked much like Figure 1, because (as was shown above) SPX option net demands are dominated by put net demands and put-call parity ensures that (up to market frictions) put and call options with the same strike price and maturity have the same implied volatilities. For brevity, we omit this figure from the paper. Figure 2 is constructed like Figure 1 except that only calls are used to compute the excess implied volatilities and the net demands. For calls, there appears to be a negative relationship between excess implied volatilities and net demand. This relationship suggests that call net demand cannot explain the call excess implied volatilities. Proposition 2(ii) predicts, however, that it is the total demand pressure of calls and puts that matters as depicted in Figure 1. Intuitively, the large demand for puts increases the prices of puts, and, by put-call parity, this also increases the prices of calls. The relatively small negative demand for calls cannot overturn this effect.

Figure 3 compares equity option expensiveness to net demands across moneyness categories. The line in the figure plots the average equity option excess implied volatili-

---

¹⁰ The first (last) moneyness interval includes all options with moneyness less than 0.85 (greater than 1.15).

¹¹ Once again, the leftmost (rightmost) bar includes net demand for all options with moneyness less than 0.85 (greater than 1.15).

¹² We also constructed plots like Figure 1 with the net demand computed from non-market makers and/or with excess implied volatility defined as option implied volatility minus the realized volatility over the life of the option or minus a GARCH(1,1) prediction for the volatility over the life of the option. All of the variations shared the main features of Figure 1.
Figure 2: The bars show the average daily net demand for calls from public customers for SPX options in the different moneyness categories (left axis). The line is the average SPX excess call implied volatility, that is, implied volatility minus historical volatility, for each moneyness category (right axis). The data covers 1996-2001.

The first (last) moneyness interval includes all options with moneyness less than 0.90 (greater than 1.10).

ity (with respect to historical volatility) per underlying stock for six moneyness intervals over the 1996-2001 period. In particular, on each trade date for each underlying stock the average excess implied volatility is computed for all puts and calls in a moneyness interval. These excess implied volatilities are averaged across underlying stocks on each trade day for each moneyness interval. The line depicts the means of these daily averages. The excess implied volatility line is downward sloping but only varies by about 2.5% across the moneyness categories. By contrast, for the SPX options the excess implied volatility line varies by over 10% across the corresponding moneyness categories. The bars in the figure present the average daily net demand per underlying
Figure 3: The bars show the average daily net demand per underlying stock from public customers for equity options in the different moneyness categories (left axis). The line is the average equity option excess implied volatility, that is, implied volatility minus historical volatility, for each moneyness category (right axis). The data covers 1996-2001.

stock from public customers for equity options in the moneyness categories. As with the SPX options, it is clear from the figure that there is a positive relationship between the net demand and the excess implied volatilities which suggests that net demand may cause excess implied volatility. If the figure is constructed from only calls or only puts, it looks roughly the same (although the magnitudes of the bars are about half as large.)

Figure 4 plots the daily net positions (i.e., net demands) for SPX options aggregated across moneyness and maturity for public customers, firm proprietary traders, and market makers. The daily public customer net positions range from −1065 contracts to +385,750 contracts, and it tends to be larger over the first year or so of the sample.
Although the public customer net position shows a good deal of variability, it is nearly always positive and never far from zero when negative. To a large extent, the market maker net option position is close to the public customer net position reflected across the horizontal axis. This is not surprising, because on each trade date the net positions of the three groups must sum to zero and the public customers constitute a much larger share of the market than the firm proprietary traders. The firm proprietary and market maker net positions roughly move with one another. In fact, the correlation between the two time-series is 0.44 percent. This positive co-movement suggests that a non-trivial part of the firm proprietary option trading may be associated with supplying liquidity to the SPX option market. For this reason, in the empirical work below we usually define end users as public customers, although the results are similar when end users are defined as public customers plus firm proprietary traders. The correlations between the public customer time-series and those for firm proprietary traders and market makers on the other hand are, respectively, $-0.78$ and $-0.90$.

Figure 4: Time series of the daily net positions for SPX options aggregated across moneyness and maturity for public customers, firm proprietary traders, and market makers.
5 Empirical Results

Propositions 3 states that positive (negative) demand pressure on one option increases (decreases) the price of all options on the same underlying asset while proposition 4 states that demand pressure on low (high) strike options has a greater price impact on low (high) strike options.\textsuperscript{14} The empirical work in this section of the paper examines these two predictions of the model by investigating both in the SPX and equity option markets whether overall excess implied volatility is higher on trade dates where net demand for options is higher and whether the excess implied volatility skew is steeper on trade dates where the skew in the net demand for options is steeper.

5.1 Proposition 3: Excess Implied Volatility and Net Demand

In order to investigate Proposition 3, we regress a measure of excess implied volatility on a measure of option net demand:

\begin{equation}
\text{ExcessImplVol}_t = a + b \text{NetDemand}_t + \epsilon_t
\end{equation}

In this regression there is one observation for each trade date, $t$. $\text{ExcessImplVol}_t$ is the average implied volatility of SPX options on trade date $t$ minus the historical volatility of the underlying SPX index for the 60 trade dates leading up to $t$. When computing this variable, the SPX options which are included are those which have at least 25 contracts of trading volume, more than 6 and fewer than 366 calendar days to expiration, and moneyness between 0.90 and 1.05. We compute the excess implied volatility variable only from reasonably liquid options which do not have extreme moneyness or time to expiration in order to make it less noisy in light of the fact that it is computed using only one trade date.\textsuperscript{15} $\text{NetDemand}$ is the net public customer demand for all SPX options which have more than 1 calendar day to expiration and moneyness between 0.80 and 1.30. Since this variable is measured without error, there is no need to compute it only from liquid options or options with non-extreme moneyness or maturity characteristics.

Panel A of Table 2 presents the results of OLS estimation of the regression over the 1996-2001 period. The estimate for the $b$ coefficient is positive and statistically significant with a t-statistic greater than nine. The fact that this coefficient is reliably positive indicates that on average when SPX net demand is higher (lower), excess SPX implied volatilities are also higher (lower). The point estimate of 0.00000013 suggests that on average excess implied volatility increases by 0.00000013 for each additional contract of SPX net demand. Since the average net demand for SPX options is 138,602

\textsuperscript{14}Propositions 3 and 4 both require some natural conditions to be met.
\textsuperscript{15}By contrast, in the previous section of the paper, when implied volatility statistics were computed from less liquid options or options with more extreme moneyness or maturity, they were averaged over the entire sample period.
contracts, demand pressure may increase option implied volatilities on a typical day by or 1.8 percentage points. For the SPX options used to compute the dependent variable in this regression, the average expensiveness is 4.19%. Consequently, end user demand may explain over 40% of the average expensiveness of SPX options.

We next investigate the relationship between excess implied volatility and net demand in the equity option market. We do this by performing daily regressions of Equation (29) for options on cross-sections of underlying stocks which meet a number of criteria. On each trade date the initial universe of underlying stocks are the 303 which have strictly positive option volume on at least 80% of the trade days from the beginning of 1996 through the end of 2001. We then identify those underlying stocks which have two or more options with moneyness greater than or equal to 0.97 and less than or equal to 1.03, maturity greater than or equal to 15 calendar days and less than or equal to 45 calendar days, closing ask prices between 0 and 2 dollars greater than closing bid prices, at least 5 contracts of trading volume, and implied volatilities available on OptionMetrics. We also require that on at least 54 of the previous 60 trade days the underlying stocks have daily returns on CRSP and OptionMetrics that differ by less than one percent. For the underlying stocks that meet these criteria, we compute the excess implied volatility for the trade day as the average implied volatility of the options minus the sample volatility of the previous stock returns computed according to Equation (28). For both the implied volatilities and the stock returns we use the data which meet the criteria spelled out above. We multiply the net demand variable by the price volatility of the underlying stock (defined as the sample return volatility just described multiplied by the day’s closing price of the stock.) We scale the net demand in this way, because market makers are likely to be more concerned about holding net demand in their inventory when the underlying stock’s price volatility is greater.

We run the cross-sectional regression on each day and then employ the Fama-MacBeth method to compute point estimates and standard errors. We also use the Newey-West procedure to control for serial-correlation in the slope estimates. When public customer net demand is used, the slope coefficient is $4.08E-08$ with a t-statistic of 8.32. When non-market maker net demand is used, the slope coefficient is $5.91E-08$ with a t-statistic of 6.44. These findings provide empirical verification for Proposition 3.

Figure 5 plots a kernel regression estimate of the relationship between excess implied volatility and public customer net demand for underlying stocks across all trade days. The function, which is plotted from the 10th to the 90th percentile of the net demand data, clearly has a positive slope which indicates that option expensiveness is increasing in net option demand. The confidence intervals are not corrected for error correlation, so they should merely be viewed as a graphical illustration of where most of the data is concentrated. (Table2 provides a statistical test which corrects for the correlation.)
Table 2: The relationship between SPX public customer demand pressure and SPX Excess Implied Volatility relative to Historical Volatility, 1996-2001. T-statistics are in parentheses.

5.2 Proposition 4: Implied Volatility Skew and Net Demand Skew

In order to investigate Proposition 4, we regress a daily measure of the steepness of the excess implied volatility skew on the skewness in the option net demand:

\[
Excess\text{ImpliedVolSkew}_t = a + b NetDemandSkew_t + \epsilon_t. \tag{30}
\]

*ExcessImpliedVolSkew*$_t$ is the trade date $t$ skew in excess implied volatility which is defined as the difference on trade date $t$ of the average implied volatility from low moneyness options and the average implied volatility from options with moneyness close to one.\(^{16}\) For the SPX options, the low moneyness options are defined as those with moneyness between 0.90 and 0.94 which trade at least 25 contracts on trade date $t$ and have more than 14 and fewer than 46 calendar days to expiration. The options with moneyness close to one are defined as those with moneyness between 0.98 and 1.02 which meet the same volume and maturity criteria. *NetDemandSkew*$_t$ is the trade date $t$ skew in net option demand which is defined as the net demand for low moneyness options minus the net demand for high moneyness options. Specifically, this variable is set equal to the net public customer demand for options with moneyness between 0.90 and 0.98 minus the net public customer demand for options with moneyness between 0.98 and 1.05. Only options with more than 14 and fewer than 46 calendar days to expiration are included in the computation of net demand skew.

\(^{16}\)Subtracting the historical volatility from both groups of options would not change the value of this variable.
Figure 5: The solid line plots a kernel regression estimate of the relationship between excess implied volatility and public customer net demand for underlying stocks across all trade days. The dashed lines are 95% confidence intervals, not corrected for error correlation.

Panel B of Table 2 reports the OLS estimates of the skewness regression over the 1996-2001 period. Once again, the \( b \) coefficient is significantly positive, this time with a t-statistic greater than six. The coefficient estimate of 0.00000010 indicates that increasing the net demand for low moneyness options by one contract or decreasing the net demand for high moneyness options by one contracts is associated with a 0.00000010 increase in the implied volatility of low moneyness short maturity options relative to the implied volatility of short maturity options with moneyness close to one. Table 1 indicates that the net demand of public customers for SPX options with moneyness less than one exceeds that for options with moneyness greater than one by an average of 86,456 contracts per day. Consequently, on a typical day demand pressure may be associated with an increase in the implied volatility of low moneyness
relative to intermediate moneyness options of on the order of 1 percent.\footnote{One standard deviation of the distribution of daily net public customer demands is 89,827 contracts.}

We also investigate whether the equity options exhibit a positive relationship between the implied volatility skew and the skew in end user demand. In order to do this, we identify on each trade day underlying stocks which have valid OptionMetrics implied volatility on both low moneyness options (defined as moneyness greater than 0.85 and less than 0.95 with 15 to 45 calendar days to maturity) and ATM options (defined as moneyness greater than 0.97 and less than 1.03 also with 15 to 45 calendar days to maturity). The implied volatility skew for an underlying stock on a trade day is then defined as the average implied volatility for the low moneyness options minus the average implied volatility for the ATM options divided by the average implied volatility for the ATM options. As before, we multiply the net demand by the price volatility of the underlying stock. The net demand skew is defined as the net demand on the low moneyness options minus the net demand on the ATM options. Running daily cross-sectional regressions for Equation (30) once again computing point estimates and standard errors using the Fama-MacBeth method and correcting for serial correlation via Newey-West, we find a slope estimate of $4.5E - 09$ with a t-statistic of 2.23 when we use public customer net demand and a point estimate of $7.1E - 09$ with a t-statistic of 3.33 when we use non-market maker net demand.

The results in this subsection indicate that in accordance with Proposition 4 there is a positive relationship between the implied volatility skew and the skew in net demand in both the SPX and equity option markets.

6 Conclusion

Relative to the Black-Scholes-Merton benchmark, index and equity options display a number of robust pricing anomalies. A great deal of research has attempted to address these anomalies, in large part by generalizing the Black-Scholes-Merton assumption about the dynamics of the underlying asset. While these effort have met with some success, non-trivial pricing puzzles remain. Further, it is not clear that this approach can yield a satisfactory description of option prices. For example, index and equity option prices display very different anomalies, although the dynamics of their underlying assets are quite similar.

This paper takes a different approach to option pricing. We recognize that in contrast to the Black-Scholes-Merton framework, in the real world options cannot be perfectly hedged. Consequently, if intermediaries such as market makers and proprietary traders who take the other side of end-user option demand are risk-averse, end user demand for options will impact option prices.
The theoretical part of the paper develops a model of competitive risk-averse intermediaries who cannot perfectly hedge their option positions. We compute equilibrium prices as a function of net end-user demand and show that demand for an option increases its price by an amount proportional to the variance of the unhedgeable part of the option and that it changes the prices of other options on the same underlying asset by an amount proportional to the covariance of their unhedgeable parts.

The empirical part of the paper measures the expensiveness of an option as its Black-Scholes implied volatility minus a proxy for the expected volatility over the life of the option. We show that on average index options are quite expensive by this measure, and that they have high positive end-user demand. Equity options, on the other hand, on average are slightly inexpensive and have small negative end user demand. In accordance with our theory’s predictions, we find that both in the index and equity option markets options are overall more expensive when there is more end-user demand for options and that the expensiveness skew across moneyness is positively related to net end-user demand across moneyness.
A Appendix

Proof of Lemma 1:

Note first that the boundedness of all the random variables considered (with the exception of $S$) ensures that all expectations are finite.

The Bellman equation is

$$J(W_t; t, X_t) = -\frac{1}{k}e^{-k(W_t + f_t(d_t, X_t))}$$

$$= \max_{C_t, q_t, \theta_t} \left\{ -\frac{1}{\gamma}e^{-\gamma C_t} + \rho E_t [J(W_{t+1}; t+1, X_{t+1})] \right\}$$

(31)

Given the strict concavity of the utility function, the maximum is characterized by the first-order conditions (FOC’s). Using the proposed functional form for the value function, the FOC for $C_t$ is

$$0 = e^{-\gamma C_t} + kr\rho E_t [J(W_{t+1}; t+1, X_{t+1})]$$

(32)

which together with (31) yields

$$0 = e^{-\gamma C_t} + kr \left[ J(W_t; t, X_t) + \frac{1}{\gamma}e^{-\gamma C_t} \right]$$

(33)

that is,

$$e^{-\gamma C_t} = e^{-k(W_t + f_t(d_t, X_t))}$$

(34)

implying (4). The FOC’s for $\theta_t$ and $q_t$ are (5) and (6). We derive $f$ recursively as follows. First, we let $f(t+1, \cdot)$ be given. Then, $\theta_t$ and $q_t$ are given as the unique solutions to Equations (5) and (6). Clearly, $\theta_t$ and $q_t$ do not depend on the wealth $W_t$. Further, (33) implies that

$$0 = e^{-\gamma C_t} - r\rho E_t \left[ e^{-k(y_{t+1} + (W_t - C_t)r + q_t(p_{t+1} - r p_t) + \theta_t R_t + f_t + f_t(d_t, X_{t+1}))} \right]$$

(35)

that is,

$$e^{-\gamma C_t} - krC_t + krW_t = r\rho E_t \left[ e^{-k(y_{t+1} + q_t(p_{t+1} - r p_t) + \theta_t R_t + f_t + f_t(d_t, X_{t+1}))} \right]$$

(36)

which, using (4), yields the equation that defines $f_t(d_t, X_t)$ (since $X_t$ is Markov):

$$e^{-kr f_t(d_t, X_t)} = r\rho E_t \left[ e^{-k(y_{t+1} + q_t(p_{t+1} - r p_t) + \theta_t R_t + f_t + f_t(d_t, X_{t+1}))} \right]$$

(37)
At \( t = T \), we want to show the existence of a stationary solution. First note that the operator \( A \) defined by

\[
AF(w; x) = \max_{C, \theta} \left\{ \frac{1}{\gamma} e^{-\gamma C} + \rho E_t \left[ F(W_{t+1}, X_{t+1}) \mid W_t = w, X_t = x \right] \right\}
\]

subject to

\[
W_{t+1} = y_{t+1} + (W_t - C)r + \theta R_{t+1}^e,
\]

satisfies the conditions of Blackwell’s Theorem, and is therefore a contraction.

Furthermore, \( AF \) maps any function of the type

\[
F(w; x) = -\frac{1}{k} e^{-kw} g(x)
\]

into a function of the same type, implying that the restriction of \( A \) to \( g \), denoted also by \( A \), is a contraction as well.

We now show that there exists \( m > 0 \) such that \( A \) maps the set

\[
G^m = \{ g : \mathbb{X} \to \mathbb{R} : g \text{ is continuous, } g \geq m \}
\]

into itself.

Continuity holds by assumption (the Feller property). Let us look for \( m > 0 \). Since

\[
Ag \geq \inf_x \inf_{\theta} r \rho E \left[ e^{-k(y_{t+1} + \theta R_{t+1}^e)} g(X_{t+1})^{\frac{1}{2}} \mid X_t = x \right]
\]

\[
\geq \inf_x \inf_{\theta} r \rho E \left[ e^{-k(y_{t+1} + \theta R_{t+1}^e)} \mid X_t = x \right] \left( \min_z g(z) \right)^{\frac{1}{2}}
\]

\[
\geq B \left( \min_z g(z) \right)^{\frac{1}{2}}
\]

for a constant \( B > 0 \) (the inner infimum is a strictly positive, continuous function of \( x \in \mathbb{X} \) compact), showing that the assertion for any \( m \) not bigger than \( B e^{-\frac{1}{2}} \).

Since \( G^m \) is complete, we conclude that \( A \) has a (unique) fixed point in \( G^m \) (which, therefore, is not 0).

It remains to prove that, given our candidate consumption and investment policy,

\[
\lim_{t \to \infty} E \left[ \rho^t e^{-kW_t} \right] = 0.
\]

Start by noting that, for \( t > T \),

\[
W_{t+1} = W_t - (r - 1) f(X_t) + y_{t+1} + \theta_t R_{t+1}^e,
\]

implying, by a repeated application of the iterated expectations, that

\[
E_T \left[ e^{-k(W_t + f(X_t))} \right] = e^{-k(W_T + f(X_T))},
\]

28
which is bounded. Since \( f(X_t) \) is bounded, it follows that \( \lim_{t \to -\infty} E[\rho^{-t}e^{-kW_t}] = 0 \).

The verification argument is standard, and particularly easy in this case given the boundedness of \( g \).

\[ \square \]

**Proof of Proposition 1:**

Given a position process from date \( t \) onwards and a price process from date \( t+1 \) onward, the price at time \( t \) is determined by (6). It is immediate that \( p_t \) is measurable with respect to time-\( t \) information.

\[ \square \]

**Proof of Proposition 2:**

Part (i) is immediate, since prices are linear. Part (ii) follows because, for any \( a \in \mathbb{R} \), the pricing kernel is kept exactly the same by the offsetting change in \((q, \theta)\).

\[ \square \]

**Proof of Proposition 3:**

Part a) follows immediately from the Cauchy-Schwarz inequality, so we offer a proof of part b). The proof is based on the following result.

**Lemma 2** Given \( h_1 \) and \( h_2 \) convex functions on \( \mathbb{R} \), \( \forall \beta < 0, \alpha, \gamma \in \mathbb{R} \), \( \exists \alpha', \gamma' \in \mathbb{R} \) such that

\[ |h_1(x) - \alpha'x - \gamma'| \leq |h_1(x) - \alpha x - \beta h_2(x) - \gamma| \]

\( \forall x \in \mathbb{R} \). Consequently, under any distribution, regressing \( h_1 \) on \( h_2 \) and the identity function results in a positive coefficient on \( h_2 \).

Letting \( \hat{p}_{t+1} = p_{t+1} - E_t \left[ p_t + 1 \right] \) and suppressing subscripts, consider the expression

\[ \Psi = E^d \left[ \hat{p}^i \hat{p}^j \right] \text{Var}(R^c) - E^d \left[ \hat{p}^i R^c \right] E^d \left[ \hat{p}^j R^c \right] \]

which we want to show to be positive. Letting \( \hat{p}^i = E^d[\hat{p}^i | S] \) and \( \hat{p}^j = E^d[\hat{p}^j | S] \), we write

\[ \Psi = E^d \left[ \text{Cov}(\hat{p}^i, \hat{p}^j | S) \text{Var}(R^c) + \hat{p}^i \hat{p}^j \text{Var}(R^c) - E^d \left[ \hat{p}^i R^c \right] E^d \left[ \hat{p}^j R^c \right] \right] \]

\[ = E^d \left[ \text{Cov}(\hat{p}^i, \hat{p}^j | S) \text{Var}(R^c) \right] + E^d \left[ \hat{p}^i \hat{p}^j \text{Var}(R^c) - E^d \left[ \hat{p}^i R^c \right] E^d \left[ \hat{p}^j R^c \right] \right] \]

The first term is positive by assumption, while the second is positive because \( \hat{p}^i \) and \( \hat{p}^j \) are convex and then using Lemma 2.

\[ \square \]
Proof of Lemma 2: We consider three cases: (i) the intersection of the graphs of \( h_1 \) and \( g \equiv \gamma + \alpha Id + \beta h_2 \) is empty; (ii) their intersection is a singleton; (iii) their intersection contains more than one point.

(i) Since the graphs do not intersect, there exists a hyperplane that separates the convex sets \( \{(x, y) : h_1(x) \leq y\} \) and \( \{(x, y) : g(x) \geq y\} \).

(ii) The same is true if the two graphs have a tangency point. If they intersect in one point, \( \hat{x} \), and are not tangent, then assume that, for \( x < \hat{x}, h_1(x) > g(x) \) (a similar argument settles the complementary case). The convex set generated by \( \{(\hat{x}, h_1(\hat{x})) \} \lor \{(x, h_1(x)) : x < \hat{x}\} \lor \{(x, g(x)) : x > \hat{x}\} \) and the one generated by \( \{(\hat{x}, h_1(\hat{x})) \} \lor \{(x, h_1(x)) : x > \hat{x}\} \lor \{(x, g(x)) : x < \hat{x}\} \) have only one point in common, and therefore can be separated with a hyperplane.

(iii) Consider the line generated by the intersection. If there existed a point \( x \) at which the ordinate of the line was higher than \( h_1(x) \) and than \( g(x) \), then it would follow that at least one of the intersection points is actually interior to \( \{(x, y) : h_1(x) \leq y\} \), which would be a contradiction. Similarly if the line was too low.

\[ \square \]

Proof of Theorem 3:
We compute the sensitivity of current prices to a deviation in future positions from 0 in the direction of \( d \) by differentiating with respect to \( \epsilon \) (evaluated at \( \epsilon = 0 \)). From the dealer’s problem it follows that

\[ p_t = E_t \left[ \rho^{s-t} e^{-\gamma(C_s-C_t)} p_s \right] \]

which implies

\[ \frac{\partial p_t}{\partial \epsilon} = E_t \left[ \rho^{s-t} e^{-\gamma(C_s-C_t)} \frac{\partial p_s}{\partial \epsilon} \right] \]

\[ = r^{-(s-t)} E_t^s \left[ \frac{\partial p_s}{\partial \epsilon} \right] \]

\[ = r^{-(s-t)} E_t^s \left[ \frac{\partial p_s}{\partial q_j^t} q_j^s \right]. \]

where we use that \( \frac{\partial C_t}{\partial \epsilon} = 0 \) at \( q = 0 \). The equality \( \frac{\partial C_s}{\partial \epsilon} = 0 \) follows from

\[ \frac{\partial C_s}{\partial q_j^s} = \frac{k \partial f(s, X_s; q)}{\gamma} = -\frac{k^2 r \rho}{\gamma} E_s^s \left[ p_{s+1} - r p_s^j + \frac{\partial \theta_s}{\partial q_s^j} R_s^{e+1} \right] = 0 \quad (38) \]

and the other equality follows from differentiating the condition that marginal rates of substitution are equal

\[ e^{-\gamma C_t} = e^{-\rho(s-t)} E_t \left[ e^{-\gamma C_s} \right], \]

30
which gives that
\[ e^{-\gamma C_t} \frac{\partial C_t}{\partial \epsilon} = e^{-\rho(s-t)} \mathbb{E}_t \left[ e^{-\gamma C_s} \frac{\partial C_s}{\partial \epsilon} \right] = 0 \]

It remains to show that the price is a smooth (\(C^\infty\)) function of \(\epsilon\). Consider a process \(d_t\) characterized by \(d_t = 0\) for all \(t > T\), and let the demand process be given by \(d_t = \epsilon_t d_t = -q_t\). At time \(t\), the following optimality conditions must hold:
\[ e^{-\gamma C_t} = (r\rho)^{T+1-t} \mathbb{E}_t \left[ e^{-k(W_{T+1}+f_{T+1})} \right] \tag{39} \]
\[ 0 = \mathbb{E}_t \left[ e^{-k(W_{T+1}+f_{T+1})} \right] \tag{40} \]
\[ 0 = \mathbb{E}_t \left[ e^{-k(W_{T+1}+f_{T+1})} \left( p_{T+1} - r^{T+1-t} p_t \right) \right] , \tag{41} \]

with
\[ W_{T+1} = (W_t - C_t) r^{T+1-t} + \sum_{s=t}^{T} (y_{s+1} - C_{s+1} + \theta_s R_{s+1}^e - \epsilon_s d_s (p_{s+1} - r p_t)) r^{T+1-s} + y_{T+1} . \]

We use the notation \(p_{T+1}\) for the time \(T+1\)-money value of the payoff of options expired by \(T + 1\).

We show by induction that, given \(X_s, (p_s, \theta_s, C_s)\) is a smooth function of \((\epsilon_s, \ldots, \epsilon_{s+1})\). Note that the statement holds trivially for \(s > T\).

Assume therefore the statement for all \(s > t\). There are \(n_t + 2\) equations in (39)–(41), with \(n_{t+1}\) being the number of derivatives priced at time \(t\). Note that the equations do not depend on \(\epsilon_s\) for \(s < t\) and that they are smooth in \(\epsilon_s\) for all \(s\), as well as in \(\theta_t\), \(C_t\), and \(p_t\). In order to prove the claim, we have to show that the derivative of the functions giving (39)–(41) with respect to \((p_t, \theta_t, C_t)\) is invertible (at \(\epsilon = 0\) suffices), i.e., it has non-zero determinant. The implicit function theorem, then, proves the induction statement for \(s = t\).

The non-zero determinant is shown as follows. If we let \(F_C, F_\theta, \) respectively \(F_q\) denote the functions implicit in equations (39)–(41), it follows easily that
\[ D_C F_C \neq 0 \]
\[ D_C F_\theta = 0 \]
\[ D_C F_q = 0 \]
\[ D_\theta F_\theta \neq 0 \]
\[ D_\theta F_q = 0 \]
\[ \text{det}(D_p F_q) \neq 0 , \]

implying that \(D_{(C_t,\theta_t, p_t)} F\) has non-zero determinant. \(\square\)
Proof of Proposition 4:

Consider an optimally hedged short put position with strike price $K < rS_t$. With $x = S_{t+1} - rS_t$, the payoff from this position is

$$
\Pi(x) = -d(K - rS_t - x)^+ + \theta x.
$$

The optimality of the hedge means that, under the risk-neutral measure,

$$
E^*[e^{-k\Pi(x)}] = 0.
$$

Note that, since $K < rS_t$, $\Pi(x) < 0$ for $x > 0$ and $\Pi(x) > 0$ for $K - rS_t < x < 0$. Consequently, given the symmetry of $x$ around 0 and the zero-expectation condition above, with $\xi$ denoting the density of $x$,

$$
\int_{-\infty}^{\infty} (e^{-k\Pi(x)}x - e^{-k\Pi(-x)}x) \xi(x) dx = -\int_{0}^{K} (e^{-k\Pi(x)}x - e^{-k\Pi(-x)}x) \xi(x) dx < 0.
$$

It immediately follows that it cannot be true that $\Pi(-x) \geq \Pi(x)$ for all $x > |K - rS_t|$. In other words, for some value $x > |K - rS_t|$, $\Pi(-x) < \Pi(x)$, which then gives $d + \theta > -\theta$, or $|\theta| < \frac{1}{2}|d|$: the payoff is more sensitive to large downward movements in the underlying than to large upward movements. Thus, there exists $\tilde{K}$ such that, for all $S_{t+1} < \tilde{K}$,

$$
P(S_{t+1} - rS_t) < P(-(S_{t+1} - rS_t)),
$$

implying that, whenever $K' < \tilde{K}$ and $K'' = 2rS_t - K'$,

$$
\begin{align*}
\quad p(p, K', d) & > p(c, K'', d) \\
\quad p(p, K', 0) & = p(c, K'', 0),
\end{align*}
$$

the second relation being the result of symmetry.

\[\square\]
